Abstract

Sometimes a complex software system fails because of errors undiscovered in the design stage of the development process. Detecting these errors early in the process would eliminate many downstream problems. The so-called “capture–recapture” model, initially used by biologists to estimate the size of wildlife populations, has been widely used to estimate the number of software design errors. However, one simplifying assumption in capture–recapture models is that the inspections performed by various inspectors are statistically independent from each other. In the paper, we propose a novel method that is based on the correlation matrix of multiple inspectors. In a numerical analysis, we show that our method outperforms other traditional models that are based on the independence assumption.

1. Introduction

Sometimes a complex software system fails because of errors, bugs, or faults introduced in the design stage of the development process. The purpose of software inspection is to detect and correct those errors before they leak through subsequent development phases and the field. Design reviews can remove some of these errors, but often a few errors remain undetected until the software is developed further. It is important to eliminate these design errors at an early stage because they become much more expensive to fix as a software system proceeds through development.
